Key words: cyanobacteria composition, nitrogen fixation, seasonality, mangrove ecosystem

Abstract—To investigate the input of combined nitrogen by cyanobacteria in mangrove ecosystems and the seasonal fluctuation of this biological process, in situ nitrogen fixation activity was measured in day and night experiments carried out at Maruhubi mangrove ecosystem adjacent to Zanzibar town. Sampling was done for 12 months at two stations: Station I covering sandy sediments and Station II muddy sediments. Associated cyanobacteria genera were identified and environmental variables were measured throughout the study period. A total of 10 genera of cyanobacteria were encountered, two of which were the heterocystous cyanobacteria genera Anabaena and Rivularia and eight the non-heterocystous genera Aphanocapsa, Merismopedia, Lyngbya, Microcoleus, Oscillatoria, Phormidium, Schizothrix and Spirulina. At both stations N₂ fixation during the night was significantly higher (P ≤ 0.05) than during the day. The average N₂-fixation rates at stations I and II were 1.64 and 1.34 nmole N₂/hr/m² respectively, with no significant differences (P ≤ 0.05) observed between seasons at both stations, or between stations in the rainy season. There was no significant correlation (P ≤ 0.05) between nitrogen fixation and physical-chemical variables, except sediment temperature, which showed a significant direct relationship with N₂ fixation rate at Station I only. The results suggest that in the investigated ecosystem cyanobacterial diversity and nitrogen fixation are high; and generally seasonal changes do not have a significant influence on nitrogen fixation. It is therefore concluded that cyanobacterial diversity and nitrogen fixation process may contribute in the promotion of primary productivity in the mangrove ecosystem adjacent to Zanzibar town.

INTRODUCTION

Mangrove ecosystem sediments are frequently characterised by dense populations of cyanobacteria, many of which are known to fix atmospheric nitrogen (Toledo et al., 1995). Nitrogen fixation is one of the important sources of combined nitrogen in mangrove ecosystems (Hicks & Sylvester, 1985). In nature, the process of nitrogen fixation is important in counterbalancing losses of combined nitrogen from the environment by dinitrification (Villbrandt et al., 1991). The reduction of atmospheric nitrogen is catalysed by the enzyme-complex nitrogenase that occurs in prokaryotic organisms such as cyanobacteria (Stal, 2000).

Nitrogen fixation in mangroves, first described by Zuberer & Silver (1974, 1978), is well documented in several mangrove communities (Potts, 1984). For example Potts (1979) measured nitrogen fixation on sediment surfaces of Sinai mangrove forests, and found a mean rate of 8.6 ¡g N/m²/d. Boto & Robertson (1991) reported a mean rate of 1.45 ¡g N/m²/d in mangrove ecosystem
sediments of Hinchinbrook, Australia. Other components such as bark, leaf litter, logs, pneumatophores and prop roots have shown nitrogen-fixing abilities related to the abundance of epiphytic cyanobacteria (Potts, 1979). In Sinai, Potts (1979) found high rates of nitrogen fixation on pneumatophores covered with cyanobacteria. In a coastal lagoon in Kenya, Woitchek et al. (1997) found that biological nitrogen fixation account for between 13 and 21% of the maximum nitrogen mobilised from decaying mangrove leaves. In the north of Lapaz, Baja California Sur, Mexico, Toledo et al. (1995) observed seasonal fluctuations in *in situ* nitrogen fixation by cyanobacteria growing on surrounding sediments on the mangrove pneumatophores. According to their findings, nitrogen fixation was low during winter, increased in early summer and reached a peak in mid summer. In addition, light and temperature were found to be the primary environmental factors governing nitrogen fixation on pneumatophores. However, more information is needed on the seasonal effects of nitrogen fixation in mangrove ecosystems of Zanzibar Island.

Mangroves are among the most productive ecosystems in marine and estuarine environments (Robertson, 1986; Alongi et al., 1992). According to Shunula & Whittick (1996), mangrove density and distribution in Tanzania is influenced by several factors, including anthropogenic activities and nutrient availability. Due to rapid increase of population and economic activities along the coast, some of the Tanzanian mangrove ecosystems, especially those near urban centres, have been under threat from anthropogenic disturbances (Semesi, 1991; Semesi et al., 1999). So far, little is known about nitrogen fixation in Tanzanian mangroves.

The specific objectives of this study were to (i) assess the impact of seasonality on *in situ* nitrogen fixation rate, and (ii) identify the cyanobacterial genera from the cyanobacterial mats associated with mangrove ecosystem sediments. The study was carried out in a mangrove ecosystem adjacent to Zanzibar Town.

**MATERIALS AND METHODS**

**Area of investigation**

Maruhubi mangrove ecosystem was selected as the study site. This area is adjacent to Zanzibar town, on the west coast of the Unguja Island (Fig. 1). The ecosystem is subject to high human impact and disturbances. Cyanobacterial mats cover the sediments surrounding the mangrove communities of this area.

**Sampling**

Sampling was done at two stations where the cyanobacterial mats were covering sandy sediments (Station I) and muddy sediments (Station II) respectively. Station I is situated west of Funguni creek outlet, while Station II is situated in the middle of the same creek (Fig. 1). Preliminary sampling was carried out during January–March 1999, when sampling stations and research methods were also established. Regular sampling at the study site commenced in April 1999 and continued until March 2000. Sampling was always done twice a month, during the neap and/or spring low tides.

**Cyanobacteria identification**

Biofilms or microbial mats with sediments were taken from cores collected as described below, for identification of cyanobacteria in the laboratory using light microscopy (BHT system Olympus, Japan). Cyanobacteria were identified to genus level as described by Rippka et al. (1979).

**In situ measurements of nitrogen fixation activity**

In the field, nitrogen fixation rates in the exposed benthic sediments associated with cyanobacteria were evaluated during the day and night at low tide twice a month, using the acetylene reduction assay (ARA) in plexiglass cores by the Bell-Jar Method described in Stal (1988).

At each sampling station, 3–4 plexiglass cores (49.4 mm diameter, 400 or 600 ml total volume) with two rubber stoppers for sealing top-cover and syringe injection port (1 cm diameter, hole just
Fig. 1. Maruhubi mangrove area in Unguja Island, showing sampling stations. Inset: Study site is indicated by the arrow.
below the top-seal, for gas injection and withdrawal) were used. One core was used as a control to see whether ethylene gas was produced from the sediments without the addition of acetylene gas. The cores were pressed into the sediment randomly over an area of 1 m² until about 1/3 of the core length remained above the sediment surface. 10% of the air phase was withdrawn from the core using a syringe, and replaced by the same volume of acetylene gas generated from calcium carbide as described by Burris (1974). After two hours incubation, the gas phase was withdrawn using a syringe and transferred to 7, 5, or 4 ml pre-evacuated vacutainers (Becton-Dickinson). In the field the vacutainers were wrapped in plastic bags and kept on ice.

In the laboratory, samples were kept at room temperature in darkness for later gas chromatography. One millilitre (1 ml) gas samples were taken from each vacutainer and analysed for ethylene content using a SHIMADZU GC-8AIF (Japan) gas chromatograph equipped with a flame ionisation detector and coupled to a computer running the CSW-Chromatography Station for Windows 1.7 software. The 3-m column was packed with Porapak R (50–80 mesh), and held at 50 ºC during analysis. The injector and detector temperatures were 150 and 120 ºC respectively. Nitrogen served as a carrier gas at a pressure of 70 kPa. The pressure of hydrogen and air were 60 and 50 kPa, respectively. Pure ethylene (100 ppm, AGA, Sweden) was used as standard gas. Peak areas were used to calculate ethylene content as described by Jonsson (1988). The values were divided by 2 hrs of incubation as well as core area, and expressed as nmol C₂H₄ produced per area per hour. For calculations of fixed nitrogen, ethylene values were divided by the theoretical conversion factor of four (Jonsson, 1988).

Assessment of environmental variables and nitrate-N concentration

Environmental variables were measured and recorded at each sampling station during the daylight at low tide before the incubations. Light intensity (in µmol photons/m²/s) was measured using a light meter (Hansatech QTP1 9521). Air and sediment temperatures (in ºC) were also recorded. Rainfall data were taken from the meteorology department of Zanzibar, pH was determined using a pH meter (Ω, Metrohm, Switzerland) and salinity was measured in the field using a handheld refractometer (ATAGOS, Japan).

Nitrate-N from sediments pore water samples was determined as described in Parsons et al. (1989). For each station, field sampling of sediments involved five parallel transects, 10 m apart. The transects at each station ran from the west bank of Funguni creek to the interior of the mangrove forest. For each sampling transect, six sampling points were established, 10 m from one another. At each sampling point along the transect, a core of 79.4 mm diameter was used to collect sediments 5 cm deep. Sediments were kept on ice and transferred to the laboratory in plastic bags. In the laboratory sediment samples were centrifuged at 3000 rpm x g for 10 minutes. Pore water of about 100 ml was extracted from the sediments at each station. The pore water was filtered through a 0.45 µm filter. If not analysed immediately, the prepared samples for nitrate determination were kept frozen at −20 ºC until analysis (Johnstone & Preston, 1993).

Statistical analysis

All in situ incubation experiments and sampling were performed in triplicate. For statistical analysis the GraphPad Software package (GraphPad Software, USA) was used. Differences in nitrogen fixation rates between sampling seasons, day and night as well as stations were determined by Wilcoxon’s paired sample test. Spearman Rank Correlations (rₛ) were performed to test for statistical relationships between nitrogen fixation rates and environmental variables for both study stations.

RESULTS

Cyanobacterial composition

A total of 10 genera of cyanobacteria were encountered; 8 non-heterocystous and 2 heterocystous. The former also had significantly higher frequency at both stations (P < 0.05, Wilcoxon’s paired sample test). There was no
significant difference in the diversity of the two types of cyanobacterial groups between stations. The eight non-heterocystous genera found were *Aphanocapsa, Merismopedia, Lyngbya, Microcoleus, Oscillatoria, Phormidium, Schizothrix* and *Spirulina* and the two heterocystous genera were *Anabaena* and *Rivularia*. In general microbial mats in sandy as well as muddy sediments were dominated (up to 90%) by one or two cyanobacterial genera. Description of the cyanobacterial species is based on morphology, the months in which they were observed and other field characteristic features noted.

**Non-heterocystous cyanobacteria**

**Order Chroococcales, Family Microcystaceae**

The following genera were found:

*Aphanocapsa*

One species was identified.

*Aphanocapsa* sp. formed blue-green films on sandy and muddy sediments and was also found on leaf litter. However, it was uncommon, found only during the months of September and December 1999. Its cells were spherical without sheath, and about 4.4–6.0 µm in diameter.

*Merismopedia*

One species was identified.

*Merismopedia* sp. was observed to form blue-green films on sandy sediments and it was uncommon, found only during the months of April, August and November 1999. Cells were about 3.0–µm wide and 6.5 µm long, aggregating to form cubical or rectangular colonies with no sheath.

**Order Oscillatoriales, Family Oscillatoriaceae**

The following genera were found:

*Lyngbya*

Two species were identified.

*Lyngbya* sp. 1 was found to form blue-green films on muddy and sandy sediments. It was found throughout the study duration. Its cells were 11.9–14.5 µm wide and 2.5–4.2 µm long, with a firm sheath around the filaments.

*Lyngbya* sp. 2 formed blue-green hair-like filaments on muddy and sandy sediments. However, it was uncommon, found only in January and March 2000. Its cells were about 14.8–17.5 µm wide and 1.8–2.7 µm long with a firm sheath, and the terminal cells were round.

*Oscillatoria*

Seven species were identified.

*Oscillatoria* sp. 1 formed brownish-green films on muddy and sandy sediments. It was common throughout the whole sampling period except in April 1999. Cells were 14.4–18 µm wide and 2.6–5.7 µm long and slightly constricted at cross walls.

*Oscillatoria* sp. 2 formed brown or olive-green mats on muddy and sandy sediments and was uncommon, found only in June and July 1999. Its cells were 20–25 µm wide and 2.5–4 µm long. Terminal cells were round and not constricted at cross walls.

*Oscillatoria* sp. 3 formed brownish-green mats on muddy and sandy sediments. It was common, found throughout the sampling period. Its cells were 9.4–13.0 µm wide and 2.4–3.0 µm long with round terminal cells.

*Oscillatoria* sp. 4 formed dark-green films on muddy and sandy sediments. It was common and found throughout the study duration. Its cells were 10–13.4 µm wide and 3.2–6.2 µm long. Terminal cells were round.

*Oscillatoria* sp. 5 formed olive-green films on muddy and sandy sediments. It was common,
found throughout the study duration. Its cells were 7–10 μm wide and 2.5–6.1 μm long. Terminal cells were not round.

*Oscillatoria* sp. 6 formed green films on sandy sediments. It was uncommon, found only during August and September 1999. Its cells were 6.1–8.0 μm wide and 6–9.5 μm long and slightly constricted at cross walls.

*Oscillatoria* sp. 7 formed blue-green films on muddy and sandy sediments. It was uncommon, found only during February and March 2000. Cells were 3.2-μm wide and 6.5 μm long and arranged close together in cubical or rectangular colonies with no sheath.

*Phormidium*

Two species were identified.

*Phormidium* sp. 1 formed green films on muddy and sandy sediments. It was common, found throughout the study duration. Its cells were 1.7–2.1 μm wide and 1.5–5.0 μm long, with rounded terminal cells in the filament.

*Phormidium* sp. 2 formed green films on muddy and sandy sediments. It was common, found throughout the study duration. Its cells were 2.7–3.4 μm wide and up to 6.5 μm long, with rounded terminal cells of the filaments.

*Schizothrix*

One species was identified.

*Schizothrix* sp. formed blue-green mats on muddy and sandy sediments. It was commonly found during October–December 1999. Cells were 6.5–10.5 μm wide and 3.2–10.5 μm long, forming short filaments without a surrounding sheath. Terminal cells of the filaments were cylindrical or rounded.

* Spirulina*

Three species were identified.

*Spirulina* sp. 1 formed brown or green films on muddy and sandy sediments. It was common throughout the sampling period. Filaments were 1.2–1.6 μm wide, forming loosely packed spirals 2.5–3.4 μm wide and 2.5–3.3 μm apart.

*Spirulina* sp. 2 formed green films on muddy and sandy sediments. It was common, found throughout the whole sampling period. Its filaments were 0.5–1.0 μm wide, forming loosely packed spirals, 1.2–1.6 μm wide and 1.5–2.4 μm apart.

*Heterocystous cyanobacteria*

ORDER NOSTOCALES, FAMILY NOSTOCACEAE

The following genera were found:

*Anabaena*

Two species were identified.

*Anabaena* sp. 1 formed olive/green films on muddy and sandy sediments. It was common and found throughout the sampling period. Its filaments consisted of spherical cells, 5.0–6.0 μm wide and 4.9–6.0 μm long. Heterocysts were 5.0–6.1 μm wide and 5.0–8.7 μm long.

*Anabaena* sp. 2 formed blue-green films on muddy sediments. It was found throughout the sampling period. Its cells were spherical, 6.0–6.5 μm wide, 3.9–7.0 μm long, and the heterocysts 6.5–7.3 μm wide and 6.5–9.7 μm long. The terminal cells were rounded.

*Rivularia*

One species was identified.

*Rivularia* sp. formed brownish films on muddy sediments. It was uncommon, found only in January and February 2000. The diameters of the heterocysts were about 8.7 μm.

**Nitrogen fixation**

The nitrogen fixation rates recorded from day and night *in situ* measurements on sandy (Station I) and muddy (Station II) sediments are presented in Fig. 2. The average N₂-fixation rate at station I was 1.64 nmole N₂/hr/m², while at station II, it was 1.34 nmole N₂/hr/m².

At station I, the nitrogen fixation rate during the night was significantly higher (Wilcoxon’s paired sample test: W = -236, n = 24 and P = 0.001) than during the day. Similarly at station II, the significantly higher (W = -196, n = 24 and P = 0.005) nitrogen fixation rate was observed during the night than during the day. The difference in nitrogen fixation rate between dry and rainy

The Spearman Rank Correlation test (Table 3) shows that generally there was no significant correlation between \textit{in situ} nitrogen fixation and physical-chemical variables, except for sediment temperature, which showed a significant direct relationship with N$_2$ fixation rate at Station I.

**DISCUSSION**

The cyanobacterial community composition results observed in this study can be compared with those of Lugomela et al. (2001) from a study performed at Mazizini also close to Zanzibar town. However, in this study more genera of filamentous non-heterocystous than heterocystous cyanobacteria are reported.

Our observation correlates well with the high N$_2$-fixation rate observed during night times and low nitrogen fixation observed during the daytimes in both stations. Several studies (Rippka et al., 1979; Stal & Krumbein, 1985; Bergman et al., 1997; Stal, 2000; Lundgren et al., 2001) show that unlike heterocystous cyanobacteria, which fix nitrogen during the day, most non-heterocystous cyanobacteria exercise a temporal separation of oxygenic photosynthesis and nitrogen fixation, with the former occurring during the day and the latter at night.

The non-heterocystous cyanobacteria in this study were more frequent and abundant compared to heterocystous cyanobacteria at both stations. There are no obvious explanations for this and more work is needed. A similar observation has been reported by Stal & Krumbein (1985), who indicate that mat-forming heterocystous cyanobacterial species occur in very low frequencies due to their poorer adaptation to the environmental conditions in the mats, leading to less successful competition with other cyanobacteria. Our finding of no significant differences in the diversity of cyanobacterial groups between sandy and muddy sediments agrees with other studies showing that cyanobacteria are a diverse group of prokaryotes able to live under a wide range of environmental conditions (Fay, 1992; Stal et al., 1985; and Whitton & Potts, 2000).

We found no statistically significant differences in nitrogen fixation between seasons at the stations and no significant relationship between \textit{in situ} nitrogen fixation rates and physical-chemical variables (except sediment temperature, at Station I). Again, an explanation of these observations is impossible without further study. In the subtropical Balandra coastal lagoon at La Paz, Baja California Sur, Mexico \textit{in situ} nitrogen fixation in summer was higher than in winter and temperature and light intensity were the primary environmental factors governing nitrogen fixation on mangrove pneumatophores (Toledo et al., 1995). This is similar to our observations on sandy sediments at Station I.

This study indicates that differences in nitrogen fixation rates between stations were only significant during the dry season. Differences in other limiting nutrients, such as phosphate, which was not investigated in this study, or of available combined nitrogen measured as nitrate, may play a role. Paerl (1996) showed that low nitrogen:

phosphorous (N: P) ratios in ecosystems, often caused by excessive anthropogenic phosphate loading, enhance cyanobacterial growth. This stimulates higher nitrogen fixation rates in a given ecosystem. A report by Fredriksson (1996) shows that less combined nitrogen in an ecosystem increases the promotion of nitrogenase synthesis in cyanobacteria, and thus nitrogenase activity. In the present study, the observed higher nitrogen fixation rate at station I than that observed at station II during the dry season could be related to the low nitrate observed at station I and high nitrate observed at station II, although statistical analysis shows no significant correlation between nitrogen fixation and nitrate in this system.

The data presented here demonstrate considerably higher cyanobacterial diversity and nitrogen fixation rate in a mangrove ecosystem of Zanzibar Island than previously reported and indicates that, generally, seasonal changes do not influence the rate of nitrogen fixation. Additional studies are required to assess the influence of other factors, such as the effect of phosphate loading from the neighbouring Zanzibar town. In addition, further studies are needed to more accurately determine the primary productivity of the ecosystem.

Acknowledgements—Our sincere gratitude is expressed to Drs Julius Francis (former IMS Director), M. Mtorela (former IMS Associate and Acting Director), M. Björk, C. Lugomela, E. Söderbäck and A. Dubi (Director, IMS) for their helpful assistance. We are also grateful to the Institute of Marine Sciences, Zanzibar; Applied Microbiology Unit of University of Dar es Salaam; and Department of Botany, Stockholm University, for use of their facilities. We extend our thanks to the Swedish Agency for Research Cooperation (SIDA/SAREC) for the financial support which made this research possible. Finally, we are very grateful to the reviewers for their constructive comments, which significantly improved the manuscript.
